Package limSolve, solving linear inverse models in R

Karline Soetaert, Karel Van den Meersche and Dick van Oevelen

Centre for Estuarine and Marine Ecology Netherlands Institute of Ecology The Netherlands

Abstract

R package **limSolve** (Soetaert, Van den Meersche, and van Oevelen 2008) solves linear inverse models (LIM), consisting of linear equality and or linear inequality conditions, which may be supplemented with approximate linear equations, or a target (cost, profit) function. Depending on the determinacy of these models, they can be solved by least squares or linear programming techniques, by calculating ranges of unknowns or by randomly sampling the feasible solution space.

Amongst the possible scientific applications are: food web quantification (ecology), flux balance analysis (e.g. quantification of metabolic networks, systems biology), compositional estimation (ecology, chemistry,...), and operations research problems. Package **limSolve** contains examples of these four application domains.

Keywords: Linear inverse models, food web models, flux balance analysis, linear programming, quadratic programming, R.

1. Introduction

In matrix notation, linear inverse problems are defined as: ¹

$$\mathbf{A} \cdot \mathbf{x} \simeq \mathbf{b}$$
 (1)

$$\mathbf{E} \cdot \mathbf{x} = \mathbf{f} \qquad (2)$$

$$\mathbf{G} \cdot \mathbf{x} > \mathbf{h} \tag{3}$$

There are three sets of linear equations: equalities that have to be met as closely as possible (1), equalities that have to be met exactly (2) and inequalities (3).

Depending on the active set of equalities (2) and constraints (3), the system may either be underdetermined, even determined, or overdetermined. Solving these problems requires different mathematical techniques.

2. Even determined systems

An even determined problem has as many (independent and consistent) equations as unknowns. There is only one solution that satisfies the equations exactly.

¹notations: vectors and matrices are in **bold**; scalars in normal font. Vectors are indicated with a small letter; matrices with capital letter.

Even determined systems that do not comprise inequalities, can be solved with R function solve, or -more generally- with **limSolve** function Solve. The latter is based on the Moore-Penrose generalised inverse method, and can solve any linear system of equations. In case the model is even determined, and if **E** is square and positive definite, Solve returns the same solution as function solve. The function uses function ginv from package **MASS** (Venables and Ripley 2002).

Consider the following set of linear equations:

which, in matrix notation is:

$$\begin{bmatrix} 3 & 2 & 1 \\ 1 & 0 & 0 \\ 2 & 0 & 2 \end{bmatrix} \cdot \mathbf{X} = \begin{bmatrix} 2 \\ 1 \\ 8 \end{bmatrix}$$

where $\mathbf{X} = [x_1, x_2, x_3]^T$.

In R we write:

[1]

1 - 2 3

In the next example, an additional equation, which is a linear combination of the first two is added to the model (i.e. $eq_4 = eq_1 + eq_2$).

As one set of equations is redundant, this problem is equivalent to the previous one. It is even determined although it contains 4 equations and only 3 unknowns.

As the input matrix is not square, this model can only be solved with function Solve

$$\begin{bmatrix} 3 & 2 & 1 \\ 1 & 0 & 0 \\ 2 & 0 & 2 \\ 4 & 2 & 1 \end{bmatrix} \cdot \mathbf{X} = \begin{bmatrix} 2 \\ 1 \\ 8 \\ 3 \end{bmatrix}$$

```
> E2 <- rbind(E,E[1,]+E[2,])
> F2 <- c(F,F[1]+F[2])
> #solve(E2,F2) # error
> Solve(E2,F2)
```

[1] 1 -2 3

3. Overdetermined systems

Overdetermined linear systems contain more independent equations than unknowns. In this case, there is only one solution in the least squares sense, i.e. a solution that satisfies:

$$\min_{x} \|\mathbf{A} \cdot \mathbf{x} - \mathbf{b}\|^2$$

.

The least squares solution can be singled out by function lsei (least squares with equalities and inequalities).

If argument fulloutput is TRUE, this function also returns the parameter covariance matrix, which gives indication on the confidence interval and relations among the estimated unknowns.

3.1. Equalities only

If there are no inequalities, then the least squares solution can also be estimated with Solve. The following problem:

$$\begin{bmatrix} 3 & 2 & 1 \\ 1 & 0 & 0 \\ 2 & 0 & 2 \\ 0 & 1 & 0 \end{bmatrix} \cdot \mathbf{X} = \begin{bmatrix} 2 \\ 1 \\ 8 \\ 3 \end{bmatrix}$$

is solved in R as follows:

[1] "lsei"

\$covar

\$RankEq

[1] 0

\$RankApp

[1] 3

Here the residual Norm is the sum of absolute values of the residuals of the equalities that have to be met exactly $(\mathbf{E} \cdot \mathbf{x} = \mathbf{f})$ and of the violated inequalities $(\mathbf{G} \cdot \mathbf{x} \geq \mathbf{h})$. As in this case, there are none of those, this quantity is 0.

The solutionNorm is the value of the minimised quadratic function at the solution, i.e. the value of $\|\mathbf{A} \cdot \mathbf{x} - \mathbf{b}\|^2$.

The *covar* is the variance-covariance matrix of the unknowns. *RankEq* and *RankApp* give the rank of the equalities and of the approximate equalities respectively.

Alternatively, the problem can be solved by Solve:

```
> Solve(A,B)
```

[1] -1.1621622 0.8378378 4.8918919

3.2. Equalities and inequalities

If, in addition to the equalities, there are also inequalities, then lsei is the only method to find the least squares solution.

With the following inequalities:

$$x_1 - 2 \cdot x_2 < 3$$

 $x_1 - x_3 > 2$

the R-code becomes:

\$residualNorm

[1] 1.776357e-15

\$solutionNorm [1] 38.17751

\$IsError

[1] FALSE

\$type

[1] "lsei"

4. Underdetermined systems

Underdetermined linear systems contain less independent equations than unknowns. If the equations are consistent, there exist an infinite amount of solutions. To solve such models, there are several options:

- ldei finds the "least distance" (or parsimonious) solution, i.e. the one where the sum of squared unknowns is minimal
- lsei- minimises some other set of linear functions $(\mathbf{A} \cdot \mathbf{x} \simeq \mathbf{b})$ in a least squares sense.
- linp finds the solution where **one** linear function (i.e. the sum of flows) is either minimized (a "cost" function) or maximized (a "profit" function). Uses linear programming.
- xranges finds the possible ranges ([min,max]) for each unknown.
- xsample randomly samples the solution space in a Bayesian way. This method returns the conditional probability density function for each unknown.

4.1. Equalities only

We start with an example including only equalities.

Functions Solve and ldei retrieve the **parsimonious** solution, i.e. the solution for which $\sum x_i^2$ is minimal.

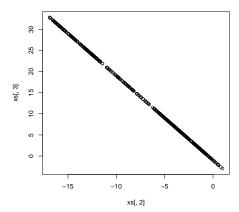

Figure 1: Random sample of the underdetermined system including only equalities. See text for explanation.

> ldei(E=E,F=F)\$X

It is slightly more complex to select the parsimonious solution using lsei. Here the approximate equations (A, the identity matrix, and b) have to be specified.

It is also possible to **randomly sample** the solution space. This demonstrates that all valid solutions of x_2 and x_3 are located on a line (figure 1).

> xs <- xsample(E=E,F=F,iter=500)\$X
> plot(xs[,2],xs[,3])

4.2. Equalities and inequalities

Consider the following set of linear equations:

$$3 \cdot x_1 + 2 \cdot x_2 + x_3 + 4 \cdot x_4 = 2$$

 $x_1 + x_2 + x_3 + x_4 = 2$

complemented with the inequalities:

As before, the **parsimonious** solution (that minimises the sum of squared flows) can be found by functions ldei and lsei.

We can also estimate the **ranges** (minimal and maximal values) of all unknowns using function xranges.

The results are conveniently plotted using R function dotchart (figure 2). We plot the parsimonious solution as a point, the range as a horizontal line.

```
> dotchart(pars,xlim=range(c(pars,xr)),label=paste("x",1:4,""))
> segments(x0=xr[,1],x1=xr[,2],y0=1:nrow(xr),y1=1:nrow(xr))
```

A random sample of the infinite amount of solutions is generated by function xsample. For small problems, the coordinates directions algorithm ("cda") is a good choice.

```
> xs <- xsample(E=E,F=F,G=G,H=H,type="cda")$X</pre>
```

To visualise its output, we use R function pairs, with a density function on the diagonal, and without plotting the upper panel (figure 3).

```
> panel.dens <- function(x, ...)
+ {
+    usr <- par("usr"); on.exit(par(usr))
+    par(usr = c(usr[1:2], 0, 1.5) )
+    DD <- density(x); DD$y<- DD$y/max(DD$y)
+    polygon(DD,col="grey")
+ }
> pairs(xs,pch=".",cex=2,upper.panel=NULL,diag.panel=panel.dens)
```

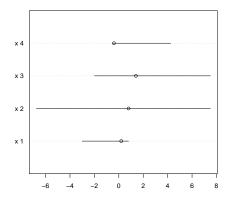

Figure 2: Parsimonious solution and ranges of the underdetermined system including equalities and inequalities. See text for explanation.

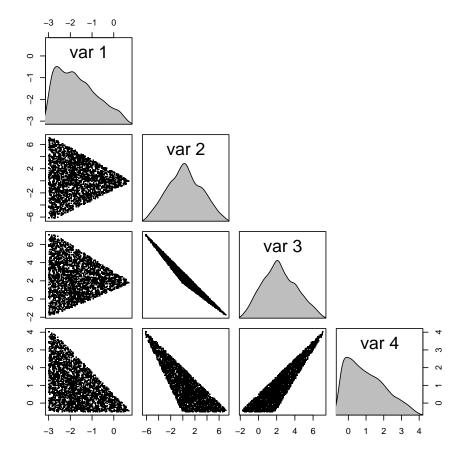

Figure 3: Random sample of the underdetermined system including equalities and inequalities. See text for explanation.

Assume that we define the following variable:

$$v_1 = x_1 + 2 \cdot x_2 - x_3 + x_4 + 2$$

We can use functions varranges and varsample to estimate its ranges and create a random sample respectively.

Variables are written as a matrix equation:

$$Va \cdot x = Vb$$

- > summary(varsample(xs,EqA=Va,EqB=Vb))

۷1

Min. :-16.2063 1st Qu.: -5.0045 Median : -0.1333 Mean : -0.3512 3rd Qu.: 4.3063 Max. : 14.6076

4.3. Equalities, inequalities and approximate equations

The following problem

is implemented and solved in R as:

```
[1] 0.3333333 0.3333333 1.6666667 -0.3333333
```

Function xsample randomly samples the underdetermined problem (using the metropolis algorithm), selecting likely values given the approximate equations. The probability distribution of the latter is assumed Gaussian, with given standard deviation (argument sdB, here assumed 1).

The jump length (argument jmp) is finetuned such that a sufficient number of trials (~30%), but not too many, is accepted. Note how the ultimate distribution is determined both by the inequality constraints (the sharp edges) as well as by the approximate equations (figure 4).

```
> panel.dens <- function(x, ...)
+ {
+     usr <- par("usr"); on.exit(par(usr))
+     par(usr = c(usr[1:2], 0, 1.5) )
+     DD <- density(x); DD$y<- DD$y/max(DD$y)
+     polygon(DD,col="grey")
+ }
> xs <- xsample(E=E,F=F,G=G,H=H,A=A,B=B,jmp=0.5, sdB=1)$X
> pairs(xs,pch=".",cex=2,upper.panel=NULL,diag.panel=panel.dens)
```

4.4. Equalities and inequalities and a target function

Another way to single out one solution out of the infinite amount of valid solutions is by minimising or maximising a linear target function, using linear programming. For instance,

$$\min(x_1 + 2 \cdot x_2 - 1 \cdot x_3 + 4 \cdot x_4)$$

subject to:

is implemented in R as:

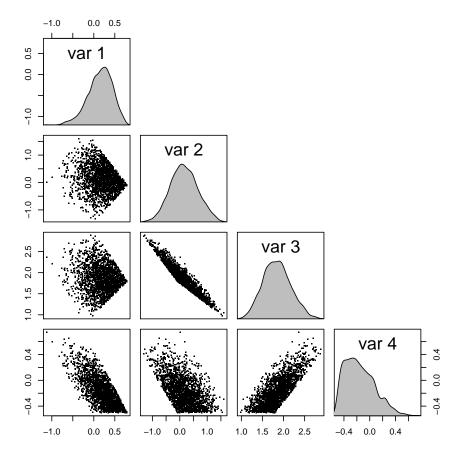

Figure 4: Random sample of the underdetermined system including equalities, inequalities, and approximate equations. See text for explanation.

The positivity requirement $(x_i \ge 0)$ is -by default- part of the linear programming problem, unless it is toggled off by setting argument ispos equal to FALSE.

```
> LP <-linp(E=E,F=F,G=G, H= H, Cost=Cost, ispos=FALSE)
> LP$X

[1] -3.00 -6.75  7.50  4.25

> LP$solutionNorm

[1] -7
```

5. datasets

There are five example applications in package limSolve :

- Blending. In this underdetermined problem, an optimal composition of a feeding mix is sought such that production costs are minimised subject to minimal nutrient constraints. The problem consists of one equality and 4 inequality conditions, and a cost function. It is solved by linear programming (linp). Feasible ranges are estimated (xranges) and feasible solutions generated (xsample)
- Chemtax. This is an overdetermined linear inverse problem, where the algal composition of a (field) sample is estimated based on (experimentally-determined) pigment

biomarkers. Biologists may know this problem as "Chemtax" (Mackey, Mackey, Higgins, and Wright 1996). See also R -package **BCE** (Van den Meersche and Soetaert 2008), (Van den Meersche, Soetaert, and Middelburg 2008). The problem contains 8 unknowns; it consists of 1 equality, 12 approximate equations, and 8 inequalities. It is solved using lsei and xsample.

- Minkdiet. This is another -underdetermined- compositional estimation problem, where the diet composition of Southeast Alaskan Mink is estimated, based on the C and N isotopic ratios of Mink and of its prey items (Ben-David, Hanley, Klein, and Schell 1997). The problem consists of 7 unknowns, 3 equations, and 7 inequalities
- RigaWeb. This is a food web problem, where food web flows of the Gulf of Riga planktonic food web in Spring are quantified (Donali, Olli, Heiskanen, and Andersen 1999). This underdetermined model comprises 26 unknowns, 14 equalities, and 45 inequalities. It is solved by lsei, xranges, and xsample.
- E_coli. This is a flux balance problem, estimating the core metabolic fluxes of Escherichia coli (Edwards, Covert, and Palsson 2002). It is the largest example included in **limSolve**. There are 70 unknowns, 54 equalities and 62 inequalities, and one function to maximise. This model is solved using lsei, linp, xranges, and xsample.

6. Notes

Package **limSolve** provides FORTRAN implementations of:

- the least distance algorithms from (Lawson and Hanson 1974) (ldp, ldei, nnls).
- the least squares with equality and inequality algorithms from (Haskell and Hanson 1978) (lsei).
- a solver for banded linear systems from LINPACK (Dongarra, Bunch, Moler, and Stewart 1979).
- a solver for tridiagonal linear systems (own implementation).

In addition, the package provides a wrapper around functions:

- function lp from package lpSolve (Berkelaar et al. 2007)
- function solve.QP from package quadprog (Weingessel 2007)

This way, similar input can be used to solve least distance, least squares and linear programming problems. Note that the packages **lpSolve** and **quadprog** provide more options than used here.

For solving linear programming problems, 1p from lpSolve is the only algorithm included. It is also the most robust linear programming algorithm we are familiar with.

For quadratic programming, we added the code lsei, which in our experience often gives a valid solution whereas other functions (including solve.QP) may fail.

Table 1: Summary of the functions in package **limSolve**

Finalisation of this package was done using R-Forge (http://r-forge.r-project.org/), the framework for R project developers, based on GForge and tortoiseSVN (http://tortoisesvn.net/) for (sub) version control.

Randomly samples a linear inverse problem for the inverse variables

This vignette was created using Sweave (Leisch 2002).

The package is on CRAN, the R-archive website ((R Development Core Team 2008))

More examples can be found in the demo of package limSolve ("demo(limSolve)")

Another R -package, LIM (Soetaert and van Oevelen 2008) 2 is designed for reading and solving linear inverse models (LIM). The model problem is formulated in text files in a way that is natural and comprehensible. LIM then converts this input into the required linear equality and inequality conditions, which can be solved by the functions in package limSolve

A list of all functions in **limSolve** is in table (1).

²at this time, this package may not yet be on CRAN; in this case it may be found on R-forge
